Chapter Three: Wave particle duality

3.1 De Broglie hypothesis

An important step in the development of a satisfactory quantum theory occurred when Louis de Broglie in 1929 in his PhD work postulated that:

- Nature is strikingly symmetrical.
- Our universe is composed entirely of light and matter.
- If light has a dual wave-particle nature, perhaps matter also has this nature.

The dual nature of light shows up in equations;

\[ \lambda = \frac{h}{p}, \quad E = h\nu \]

Each equation contains within its structure both a wave concept (\(\lambda; \nu\)), and a particle (\(p; E\)).

The photon also has an energy given by the relationship from the relativity theory

\[ E = mc^2 \quad \text{(for photon)}, \quad E = \frac{p^2}{2m} \quad \text{(for particles)} \]

Since \(E = h\nu = \frac{hc}{\lambda}\), we find the wavelength

\[ \lambda = \frac{h}{mc} = \frac{h}{p}, \]

where \(p\) is the momentum of the photon.

This does not mean that light has mass, but because mass and energy can be interconverted, it has an energy that is equivalent to some mass. De Broglie postulated that a particle can have a wave character, and predicted that the wavelength of a matter wave would also be given by the same equation that held for light, where now \(p\) would be the momentum of the particle

\[ \lambda = \frac{h}{mv} = \frac{h}{p} \]
where $v$ is the velocity of the particle.

**Example:** What is the de Broglie wavelength of an electron whose kinetic energy is $K = 100$ eV?

Calculate the velocity of the electron from which we then find the de Broglie wavelength corresponding to that velocity.

The velocity of the electron of energy 100 eV is

$$v = \sqrt{\frac{2K}{m}} = 5.9 \times 10^6 \text{ m/s}$$

Hence, the de Broglie wavelength corresponding to this velocity is

$$\lambda = \frac{\hbar}{mv} = \frac{6.63 \times 10^{-34} \text{ J.s}}{(9.11 \times 10^{-31} \text{ Kg})(5.9 \times 10^6 \text{ m})} = 1.2 \text{ Å}$$

### 3.2 Heisenberg uncertainty principle

In quantum mechanics, the Heisenberg uncertainty principle states that certain pairs of physical properties, like position and momentum, cannot both be known to arbitrary precision. That is, the more precisely one property is known, the less precisely the other can be known. According to the uncertainty principle, it is, for instance, impossible to measure simultaneously both position and velocity of a microscopic particle with any degree of accuracy or certainty.

$$\Delta x \Delta p \geq \frac{\hbar}{2}$$

$$\Delta E \Delta t \geq \frac{\hbar}{2}$$
3.3 Single slit experiment

In this section we will discuss the nature of the Fraunhofer diffraction pattern produced by a single slit. Some important features of this problem can be deduced by examining waves coming from various portions of the slit, as shown in Figure (3.1). According to Huygens principle, each portion of the slit acts as a source of waves. Hence, light from one portion of the slit can interfere with light from another portion, and the resultant intensity on the screen will depend on the angle $\theta$.

![Figure 3.1: Diffraction by single narrow slit and its intensity distribution](image)

To analyze the diffraction pattern, it is convenient to divide the slit in two halves, as in Figure (3.1). All the waves that originate from the slit are in phase. Consider waves 1 and 3, which originate from the bottom and center of the slit, respectively. Wave 1 travels farther than wave 3 by an amount equal to the path difference $(a/2)\sin\theta$, where $a$ is the width of the slit. Similarly, the path difference between waves 2 and 4 is also $(a/2)\sin\theta$. If this path difference is exactly one half of a wavelength $(\lambda/2)$, the two waves cancel each other and destructive interference results. This is true, in fact, for any two waves that originate at points separated by half the slit width because the phase difference between two such points is $180^\circ$. Therefore, waves from the upper half of the slit interfere destructively with waves from the lower half of the slit when

$$\frac{a}{2} \sin\theta = \frac{\lambda}{2}$$

or when

$$\sin\theta = \frac{\lambda}{a}$$
If we divide the slit into four parts rather than two and use similar reasoning, we find that the screen is also dark when
\[
\sin \theta = \frac{2\lambda}{a}
\]

3.4 Young’s double-slit experiment

Young originally carried out his double-slit experiment to test the wave nature of light and his simple arrangement still finds practical use in measurements of the coherence of light. Figure (3.2) shows a typical experimental layout. Waves propagate from the source slit S through the two slits, \( \Sigma_1 \) and \( \Sigma_2 \), to a point P in the detection plane equals the sum of the electric field amplitudes that arrive at that point via slits \( \Sigma_1 \) and \( \Sigma_2 \). In any interference or diffraction calculation the resultant amplitude at the final point is determined by summing the contributions from all possible paths taking account of the phase. For the double slits

![Figure 3.2: The Young’s double slit experiment](image)

we define \( \ell_1 \) as the distance from S to P via \( \Sigma_1 \), and similarly \( \ell_2 \) for the path through slit \( \Sigma_2 \), as shown by the dotted lines in Fig. 3.2 (b). Slits of the same size contribute equally to the total amplitude at a point on the plane P:

\[
E_p \propto E_o \left( e^{-i2\pi \ell_1 / \lambda} + e^{-i2\pi \ell_2 / \lambda} \right)
\]

The intensity is proportional to the square of this amplitude, \( I \propto |E|^2 \) so that

\[
I = I_0 \cos^2 \left( \frac{\phi}{2} \right)
\]
Here \( \phi = 2\pi(\ell_2 - \ell_1)/\lambda \) is the phase difference between the two arms and \( I_\theta \) is the maximum intensity. Bright fringes occur at positions in the detection plane where the contributions from the two paths interfere constructively; these correspond to \( \phi = 2n\pi \), with \( n \) an integer, or equivalently

\[
\ell_2 - \ell_1 = n\lambda
\]

To find the spacing of the fringes in the plane of observation we define the coordinate \( X \) measured perpendicular to the long axis of the slits in the plane \( P \). In terms of the small angle defined in Fig. 3.2 (b) this becomes

\[
X = L \tan \theta
\]

A similar small angle approximation allows us to express the path length difference in Fig. 3.2 (b) as

\[
\ell_2 - \ell_1 = \Delta\ell + d \sin \theta
\]

Here \( \Delta\ell = \sum S_1 - \sum S_2 \) the path difference before the slits. The path length difference from the two slits of separation \( d \) to \( P \) is \( d \sin \theta \). The last three equations give the spacing of the fringes as

\[
\Delta X = \frac{L\lambda}{d}
\]
